The observed multi-GeV gamma-ray emission from the solar disk — sourced by hadronic cosmic rays interacting with gas, and affected by complex magnetic fields — is not understood. Utilizing an improved analysis of the Fermi-LAT data that includes the first resolved imaging of the disk, we find strong evidence that this emission is produced by two separate mechanisms. Between 2010–2017 (the rise to and fall from solar maximum), the gamma-ray emission is dominated by a polar component. Between 2008–2009 (solar minimum) this component remains present, but the total emission is instead dominated by a new equatorial component with a brighter flux and harder spectrum. Most strikingly, although 6 gamma rays above 100 GeV are observed during the 1.4 years of solar minimum, none are observed during the next 7.8 years. These features, along with a 30–50 GeV spectral dip which will be discussed in a companion paper, were not anticipated by theory. To understand the underlying physics, Fermi and HAWC observations of the imminent Cycle 25 solar minimum are crucial.

The Sun is a bright source of multi-GeV  $\gamma$ -rays, with emission observed both from its halo — due to cosmic-rays electrons interacting with solar photons — and its disk — due to hadronic cosmic rays (mostly protons) interacting with solar gas. (Emission from solar particle acceleration is only bright during flares and has not been observed above 4 GeV [1–8].) Although the halo emission [9] agrees with theory [10–12], the disk emission does not, and hence is our focus.

Until recently, the most extensive analysis of solar disk  $\gamma$ -ray emission was based on Fermi-LAT data from 2008–2014 [13] (for earlier work, see Refs. [9, 14]), and produced three results. First, the flux is bright, e.g., at 10 GeV, it exceeds the flux expected from Earth-directed cosmic rays interacting with the solar limb by a factor  $\gtrsim$ 50 [15]. Second, it continues to 100 GeV, requiring proton energies ~1000 GeV. Third, the 1–10 GeV flux is anti-correlated with solar activity, and is ~2.5× larger at solar minimum than maximum. The *only* theoretical model of disk emission is the 1991 paper of Seckel, Stanev, and Gaisser (SSG) [16], which proposes that magnetic flux tubes can reverse incoming protons deep within the solar atmosphere, where they have an appreciable probability of

is detected up to  $\sim$ 30 GeV. Most significantly, we discover a spectral dip between 30–50 GeV. This dip is unexpected and its origin is unknown. Here we extend the analyses of Refs. [13, 17] by going to higher energies, studying the time variation in a new way, and performing the first analysis of flux variations across the resolved solar disk. In the following, we detail our methodology, highlight key discoveries, and discuss their possible theoretical implications.

The importance of this work is manifold. Because the disk  $\gamma$ -ray emission is brighter and more mysterious than expected, it motivates new searches with Fermi [18], the higher-energy HAWC  $\gamma$ -ray experiment [19], and the IceCube neutrino observatory [20]. The results will yield valuable insights on the complex, dynamic solar magnetic environment, from cosmic-ray modulation in the solar system to the fields deep within the photosphere. They will also advance searches for new physics [21–29]. Most generally, these searches provide the highest-energy data available in the program to understand the Sun as an example of other stars.

### Fermi Status Update

Both instruments aboard NASA's Fermi Gamma-ray Space Telescope have resumed science observations. The spacecraft itself is functioning well despite the March 16 failure of a mechanism that drives one solar panel, an event that triggered an automatic "safe hold" that powered down Fermi's instruments.

The Gamma-ray Burst Monitor (GBM) was powered back up on March 28 and has resumed normal science operations, detecting more than two dozen gamma-ray bursts since. The GBM sees the entire sky not blocked by Earth.

Fermi's primary instrument, the Large Area Telescope (LAT), was powered up on April 2 and allowed to reach its nominal temperature before observations resumed on April 8.

Currently, the observatory is using a slightly different strategy for viewing the sky. This strategy is still being optimized while the engineering team continues to study the cause of the anomalous solar panel behavior.

Since its return to duty, the LAT has detected numerous flares from active galaxies powered by supermassive black holes and saw two novas - stellar explosions occurring on white dwarf stars in our own galaxy.

"The gamma-ray sky has been quite active lately, so we're glad the LAT is back on the job," said Fermi Project Scientist Julie McEnery at NASA's Goddard Space Flight Center in Greenbelt, Maryland.

The solar disk is among the brightest  $\gamma$ -ray sources in the sky. It is also among the most mysterious. No existing model fully explains the luminosity, spectrum, time variability, and morphology of its emission. We perform the first analysis of solar-disk  $\gamma$ -rays over a full 11-year solar cycle, utilizing a powerful new method to differentiate solar signals from astrophysical backgrounds. We produce: (i) a robustly measured spectrum from 100 MeV to 100 GeV, reaching a precision of several percent in the 1–10 GeV range, (ii) new results on the anti-correlation between solar activity and  $\gamma$ -ray emission, (iii) strong constraints on short-timescale variability, ranging from hours to years, and (iv) new detections of the equatorial and polar morphologies of high-energy  $\gamma$ -rays. Intriguingly, we find no significant energy dependence in the time variability of solar-disk emission, indicating that strong magnetic-field effects close to the solar surface, rather than modulation throughout the heliosphere, must primarily control the flux and morphology of solar-disk emission.

#### I. INTRODUCTION

The Sun's  $\gamma$ -ray emission is dramatically affected by its magnetic fields. Without magnetic fields, the disk emission would have two components. At energies above  $\sim 1$  GeV, the The Sun is a special astrophysical source. Its close proxim- $\gamma$ -ray direction increasingly follows that of the parent cosmic ity allows detailed studies critical to understanding other stars. ray. Accordingly, only cosmic rays that graze the solar surface The ability to spatially resolve solar emission is especially imcan interact and have the  $\gamma$ -rays escape [14]. The correspondportant for probing high-energy, nonthermal processes, which ing emission from the solar limb is too faint to be observed can be highly local. These processes reveal charged-particle by the Fermi Gamma-Ray Space Telescope (Fermi). Near 1 acceleration and interactions in the Sun's complex, dynamic GeV, there is also a "backsplash" component from the whole magnetic fields. In addition, the "space weather" induced by disk, as kinematics allow low-energy  $\gamma$ -rays to be emitted at a these processes affects Earth's atmosphere and our technologlarge angle relative to the parent cosmic ray [15]. ical infrastructure, giving these studies practical as well as sci-Of course, the Sun does have magnetic fields.
